Lichens were once classified as single organisms—until the advent of microscopy, when the association of fungi with algae or cyanobacteria became evident. Although lichens had been assumed to consist of a single fungus species (usually an ascomycete) and a single photosynthetic partner, research suggests that many macrolichens also feature specific ...

Lichens are able to colonize places where there are extremes of humidity, temperature and light, and they often occur in places where few other macroscopic living things can survive. Found on soil, tree bark, rocks and even some under water, they are actually two organisms living together (symbiosis). The major component is a fungus (mycobiont), hence they are classified as fungi — the vast majority being ascomycetes.

While lichens function like photosynthetic plants and often compete with plants of similar size, biologically they are a symbiosis of a fungus with an alga and/or a nitrogen-fixing cyanobacterium. With few exceptions, their vegetative body, the thallus, has a morphology and physiology radically different from the symbionts growing alone.
